Range Querie and Updates

Range Trees over Trees

- Vectors are dynamic arrays
- Random access is O(1), like arrays
- A vector is stored *contiguously* in a single block of memory
- Supports an extra operation push\_back(), which adds an element to the end of the array
- STL implements a templated vector in <vector>

Range Queries and Updates

Range Tree over Trees

- Do we have enough space allocated to store this new element? If so, we're done: O(1).
- Otherwise, we need to allocate a new block of memory that is big enough to fit the new vector, and copy all of the existing elements to it.
- This is an O(n) operation when the vector has n elements. How can we improve?
- If we double the size of the vector each reallocation, we perform O(n) work once, and then O(1) work for the next n-1 operations, an average of O(1) per operation.
- We call this time complexity amortised O(1).

#### Vectors

Stacks and

Sets and Mai

Basic

Examples

Union Fin

Range Queries and Updates

Range Tree over Trees

- How is amortised complexity different from average case complexity?
- For an expected constant time operation (e.g. hash table lookup), it may still be possible for n consecutive operations to each take O(n) time, for a total time of  $O(n^2)$ .
- This is not possible with amortised complexity. An individual operation might take O(n) time, but n consecutive operations are *guaranteed* to take O(n) time in total.

Range Queries and Updates

Range Tree over Trees

- STL's  $\langle \text{set} \rangle$  is a set with  $O(\log n)$  random access
- Internally implemented as a red/black tree of set elements
- Unfortunately doesn't give you easy access to the underlying tree - iterator traverses it by infix order
- C++11 adds <unordered\_set>, which uses hashing for O(1) average case (O(n) worst case) random access
- Main advantage of <set> is it keeps the data ordered, hence has lower\_bound(x) and upper\_bound(x) which returns the next element not less than (resp. greater than) x
- $\bullet$  <multiset> and (C++11) <unordered\_multiset> are also available

Jnion-Fine

Range Queries and Updates

Range Tree over Trees

Solving Problems i Subranges • One of the main problems with set and map is they don't track index information.

 So you can't query what the k-th number is or how many numbers are < x.</li>

Most SBBSTs can be modified to track this metadata.
 But we do not want to implement a SBBST.

Range Queries and Updates

Range Tree over Trees

Solving Problems in Subranges

- There is a fix in GNU C++. So it is not a C++ standard but pretty widespread.
  - Contained in an extension called "Policy Based Data Structures".
  - In headers:

```
#include <ext/pb_ds/assoc_container.hpp>
#include <ext/pb_ds/tree_policy.hpp>
```

```
using namespace __gnu_pbds;
```

 Details are pretty technical, fortunately we don't need to know them.

Range Queries and Updates

Range Trees over Trees

Solving Problems in Subranges

### New data structure:

- Key type: int
- No mapped type (a set not a map)
- Comparison: less<int>
- rb\_tree\_tag: Implemented as a red-black tree, guarantees O(log n) performances
- tree\_order\_statistics\_node\_update. The magic: tells it to update order statistics as it goes.

Vectors

C. 1

Sets and Maps

Heaps

Basic Example:

Example

Union-Fin

Range Querie and Updates

Range Tree over Trees

Solving Problems in Subranges Essentially a set/map with 2 extra operations:

- find\_by\_order(x): Find the x-th element, 0-indexed.
- order\_of\_key(x): Output the number of elements that are < x.</li>
- Both are  $O(\log n)$  still!
- Furthermore, in other regards they still behave like a set/map!

Range Querie and Updates

Range Trees over Trees

Solving Problems in Subranges

- Supports push() and pop() operations in  $O(\log n)$ , top() in O(1).
- top() returns the value with highest priority
- Is usually used to implement a priority queue data structure
- STL implements a templated priority queue in <queue>
- The default is a max heap often we want a min heap, so we declare it as follows:

```
#include <queue>
priority_queue <T, vector<T>, greater<T>> pq;
```

• It's significantly more code to write a heap yourself, as compared to writing a stack or a queue, so it's usually not worthwhile to implement it yourself

Basic Examples

Examples

Haras Eta

Range Queries and Updates

Range Trees

Solving Problems i Subranges • The type of heaps usually used is more accurately called a binary array heap which is a binary heap stored in an array.

- It is a binary tree with two important properties:
  - Heap property: the value stored in every node is greater than the values in its children
  - Shape property: the tree is as close in shape to a complete binary tree as possible

#### Basic Examples

Basic Uses 29

#### Data Structures

Most uses fall out naturally from the use case.

• Vectors: Use everywhere.

Stacks

• When you need a LIFO structure.

 Generally when the most recent thing you've seen is most important or should be processed first.

• E.g: basic parsers, dfs, bracket matching.

• Queues:

When you need a FIFO structure.

 Generally when you want to process events in order of occurrence.

• E.g: event processing, bfs.

Solving Problems in Subranges

# Heap:

- When you find yourself asking how I can get the "largest/smallest" item.
- E.g: Dijkstra's algorithm, other greedy algorithms.

### Set:

- Seen array on unbounded keys. Also when you need to dynamically maintain a sort order.
- $\bullet$  E.g: Recognizing duplicates, find closest key to x.

# Map:

- As above but with keyed data.
- $\bullet$  E.g: Count duplicates, find index of the closest key to x.

Range Queries and Updates

Range Trees over Trees

Solving Problems in Subranges  While STL has a lot of nice functionality, it does have significant overhead. If your algorithm is of the correct time complexity but exceeds the time limit, you might achieve some constant factor speedup by removing unnecessary STL:

- Replace vectors with arrays allocate as much memory as you would ever need
- Replace stacks and queues with arrays
- Replace small sets with bitsets

Solving Problems in Subranges

#### Problem statement

There are  $n \le 2000$  countries, the *i*-th has  $a_i \le 20$  delegates.

There are  $m \le 2000$  restaurants, the *i*-th can hold  $b_i \le 100$  delegates.

For "synergy" reasons, no restaurant can hold 2 delegates from the same country.

What's the minimum number of delegates that need to starve?

Example Example

Problems
Union-Fine

Range Querie and Updates

Range Trees over Trees

Solving Problems in Subranges Old complexity was  $O(nm \log m)$ : for each of n countries, sort and sweep through a list of m restaurants.

New complexity?

- Let A be the maximum number of delegates per country.
- $O(n \cdot A \cdot \log m) \approx 2000 \times 20 \times 11 = 4.4 \times 10^5$ , one hundred times faster!
- Efficiency comes from not re-sorting the entire list of  $m \le 2000$  restaurants every round.

# Example problem: Restaurants

Sets and Mah

Heaps

Basic Examples

Example Problems

Union-Find

Range Querie and Updates

Range Trees over Trees

- Moral: Heaps keep their items *somewhat ordered*. Good for when you only need extreme values from one end.
- Moral: In a greedy algorithm, each step often involves finding the best item by some metric.
  - You don't *need* the items completely sorted to do this.
  - In any case, inserting into a sorted list takes linear time.
- **Note:** Balanced BST (i.e. set) could be used instead, as it keeps the items *completely ordered*.
  - Pro: can look up items at both extremes.
  - Pro: can look up items in the 'middle' with lower\_bound or upper\_bound (i.e. best item by the metric within some bound).
  - Con: much worse constant factor than priority\_queue.

Problems
Union-Fin

Range Queries and Updates

Range Trees

Solving Problems in Subranges • **Problem statement** You are given an array of n numbers, say  $a_0, a_1, \ldots, a_{n-1}$ . Find the number of pairs (i, j) with  $0 \le i < j \le n$  such that the corresponding subarray satisfies

$$a_i + a_{i+1} + \ldots + a_{j-1} = S$$

for some specified sum *S*.

- **Input** The size n of the array  $(1 \le n \le 100,000)$ , and the n numbers, each of absolute value up to 20,000, followed by the sum S, of absolute value up to 2,000,000,000.
- Output The number of such pairs.

- Vectors
- Stacks an
- Sets and Map

Неар

Basic Examples

Example

Problems
Union-Fin

Range Querie and Updates

Range Tree over Trees

Solving Problems in Subranges

- **Algorithm 1** Evaluate the sum of each subarray, and if it equals *S*, increment the answer.
- **Complexity** There are  $O(n^2)$  subarrays, and each takes O(n) time to add, so the time complexity is  $O(n^3)$ .
- Algorithm 2 Compute the prefix sums

$$b_i = a_0 + a_1 + \ldots + a_{i-1}.$$

Then each subarray can be summed in constant time:

$$a_i + a_{i+1} + \ldots + a_{j-1} = b_j - b_i$$
.

• Complexity This solution takes  $O(n^2)$  time, which is an improvement but still too slow.

Stacks a

Queues

Sets and Maps

. .

Basic

Example

Problems
Union-Fine

Range Queries and Updates

Range Trees over Trees

- We need to avoid counting the subarray individually.
- For each end point  $1 \le j \le n$ , we need to find how many start points i < j have the property that  $b_j b_i = S$ , i.e. how many satisfy

$$b_i = b_j - S$$
.

- If we know the frequency of each value among the  $b_i$ , we can add all the answers involving j at once.
- The values could be very large, so a simple frequency table isn't viable - use a map!

Vector

Stacks an Queues

Sets and Map

Heap:

Basic Example

Example Problems

Union-Fin

Range Querie and Updates

Range Trees

Solving Problems in Subranges • Algorithm 3 Compute the prefix sums as above. Then construct a map, and for each  $b_j$ , add the frequency of  $b_j - S$  to our answer and finally increment the frequency of  $b_j$ .

• Complexity The prefix sums take O(n) to calculate, since

$$b_{i+1}=b_i+a_i.$$

Since map operations are  $O(\log n)$ , and each  $b_j$  requires a constant number of map operations, the overall time complexity is  $O(n \log n)$ .

Range Trees

- Observation 1: We only care about maximal ranges.
   Assuming chair 0 and chair M+1 are occupied, we only care about ranges starting and ending with occupied chairs.
- So we will maintain for each chair the length of the range to its right.
- How does an update change the intervals?
- It breaks one apart into two pieces.

# Largest Interval

## Data Structures

Vectors

Stacks ar

Sets and Map

Heaps

Example:

Problems
Union-Fine

Range Queries and Updates

Range Tree over Trees

- What data do we need to store to handle updating intervals (i.e: to determine what the 2 new intervals are when we insert a chair)?
- For each update, we need to find the closest chair in both directions.
- We need to maintain a *sorted* list of chairs *associating* with each chair the length of the range starting at that chair.
- Map!
- Figuring out the new range lengths is basic maths, just be careful with off-by-1s!

Range Queries and Updates

Range Tree over Trees

Solving Problems in Subranges • Many of our data structures work best if data is sorted.

• We can put them into a set and use lower\_bound

• Or we can put them into a vector and binary search.

Sometimes we have to work a bit to get this!

Range Querie and Updates

Range Trees over Trees

- **Observation 1:** We only care about "maximal" rectangles.
- More formally, they hit some column's roof and can not be extended to the left or right.
- Many angles to approach this problem. Let us focus on one specific column's roof. We now want to find the largest histogram that hits that column's roof.
- Claim: We just need to know the first column to its left (and right) that has lower height than it.
- But we need this for all choices of our "specific column".
   So we will try to do this in a linear sweep and maintain some sort of data structure that can answer this.

Example

Problems

Range Querie

Range Trees

$$\mathsf{area}[\mathit{i}] = \mathsf{h}[\mathit{i}] \times (\mathsf{left}[\mathit{i}] + 1 + \mathsf{right}[\mathit{i}])$$

Example

Problems

- Queries: what is the first column with height < h.
- Updates: add a new column ( $pos, h_{pos}$ ) where pos is greater than all previous positions.
- Multimap? But what can we search on...?
  - If our key is height then we can find a column lower than us. But it is not guaranteed to be the closest one.
  - If our key is position then we can't do anything.
- Heap? Again, same problem (our heap can't do anything a set can't do).

Vectors

Charles

Sets and Man

Pacie

Example Example

Problems

Range Querie

Range Tree

Solving Problems i Subranges • **Key Observation:** Out of all added columns, we only care about columns that have no lower columns to their right!

 So if we only keep these columns in our map, then the first column in our map lower than us is also the closest column lower than us.

Range Queries and Updates

Range Tree over Trees

- **Complexity?** Dominated by map operations.
- O(n) calls to lower\_bound and insert.
- Each column can only be removed from the map once, so O(n) calls to erase also.
- Total time to sweep left to right is  $O(n \log n)$  (amortised  $O(\log n)$  per column).
- Repeat this right to left, and add a bit of maths to solve original problem regarding largest rectangle under histogram.

Range Queries and Updates

Range Tree over Trees

- Each sweep could be sped up to O(n) by using a stack instead of a map.
  - Inserting (pushing) and deleting (popping) go from  $O(\log n)$  to O(1).
  - Popping the stack before calculating left[i] makes the binary search unnecessary.
- Challenge: There is a beautiful algorithm that does it in one stack sweep in O(n). Essentially the same idea except process a rectangle not at the column where it attains its maximum but at the right end.
- Another famous problem using a similar idea is Longest Increasing Subsequence.

Range Trees

- A tree is a connected, undirected graph with a unique simple path between any two vertices.
- A rooted tree is one with a designated root.
  - All other vertices have a parent par[v], which is the next node in the unique path from v to the root.
- An easy way to represent a rooted tree is to just store this parent array.

Union-Find 68

# Data Structures

Also called a *system of disjoint sets*; used to represent disjoint sets of items.

Given some set of elements, support the following operations:

- union(x, y): union the disjoint sets that contain x and y
- find(x): return a canonical representative for the set that x is in
  - More specifically, we must have find(x) = find(y) whenever x and y are in the same set.
  - It is okay for this answer to change as new elements are joined to a set. It just has to remain consistent across all elements in each disjoint set at a given moment in time.

Example

Example

# Union-Find

Range Queries and Updates

Range Tree over Trees

- **Strategy:** Represent each disjoint set as a rooted tree. The representative of each rooted tree is the chosen root. For this, we just need to store the parent of each element.
- For find(x), walk up parent edges from x until a root (a vertex who is their own parent) is found
- For union(x, y), add an edge between the trees containing x and y
  - When the two trees are joined, what's the new root?
  - Don't add the edge between x and y directly
  - Instead add the edge between find(x) and find(y), and designate find(x) as the new parent of find(y)

Basic Example

Example

Union-Find

Range Queries and Updates

Range Tree over Trees

- In the basic implementation, we made find(x) the new parent of find(y), but the inverse would also be valid.
   Which one is better?
- We should hang the smaller subtree from the root of the larger subtree
- The maximum height of the tree is now  $O(\log n)$ 
  - When we traverse the edges from any particular element to its parent, we know that the subtree rooted at our current element must at least double in size, and we can double in size at most  $O(\log n)$  times
- Therefore **find** and **union** now take only  $O(\log n)$  time

### Union-Find

Range Queries and Updates

Range Tree over Trees

Solving Problems in Subranges  When performing a find operation on some element x, instead of just returning the representative, we change the parent edge of x to whatever the representative was, flattening that part of the tree

• This optimisation alone gives an amortised  $O(\log n)$  per operation complexity. Proof is nontrivial, omitted.

```
int root(int x) {
    // only roots are their own parents
    // otherwise apply path compression
    return parent[x] == x ? x : parent[x] = root(parent[x]);
}
```

vectors

Queues

Sets and Map

Неар

Example

Example

### Union-Find

Range Queries and Updates

Range Tree over Trees

Solving Problems in Subranges • Combined with the size heuristic, we get a time complexity of amortised  $O(\alpha(n))$  per operation, but the proof is very complicated.

- $\alpha(n)$  is the inverse Ackermann function, a very slow growing function which is less than 5 for  $n < 2^{2^{2^{16}}}$ .
- As mentioned, the above two optimisations together bring the time complexity down to amortised  $O(\alpha(n))$ .

# Union-Find: Path Compression

Example:

Evample

Union-Find

and Updates

Range Trees over Trees

Solving Problems in Subranges

- Warning: in practice, path compression is not as much of a speedup as you might think.
  - Without path compression, the recursive call is only ever the last instruction of the function.
  - With path compression, the value returned by this call must be assigned to another variable and then returned.
  - So path compression does not benefit from a compiler optimisation called tail recursion.

due to a low-level detail, the path compression optimisation actually significantly slows down the find function, because we lose the tail recursion optimisation, now having to return to each element to update it.

• This may overshadow the improvement from  $O(\log n)$  to  $O(\alpha(n))$ , depending on bounds of the problem.

The main application of union find.

Given a graph with  $n \le 100,000$  vertices and no edges, support  $m \le 100,000$  operations of two forms.

- update
  - denoted U a b
  - add an undirected edge between a and b
- query
  - denote Q a b
  - output 1 if a and b are connected, 0 otherwise.

Range Queries and Updates

Range Trees over Trees

Solving Problems in Subranges • When is it useful? When you need to maintain which items are in the same set.

 Main limitation: You can not delete connections, only add them. However, in a lot of natural contexts, this is not a restriction since items in the same set can be treated as the same item.

### • Extension:

- The problem of maintaining a system of disjoint sets with both insertion and deletion of connections is called dynamic connectivity.
- The offline version, where the updates and queries are provided in advance, can be solved in O(log n) per query using an advanced data structure called a link-cut tree.
- The online version is even harder, but it is possible in O(log<sup>2</sup> n) per update and O(polylog n) per query.

Range Queries and Updates

Range Tree over Trees

Solving Problems in Subranges

- Last main topic is data structures that support operations on a range
- Why do we care about this?
- Pragmatic answer: impossible to just support arbitrary queries and updates, but there is a lot of interesting stuff we can do with ranges.
- But also, naturally applies to many problems, e.g: ranges of numbers, a range in an array, linear sweeps often result in caring about ranges ...

Vectors

Union-Fin

Range Queries and Updates

Range Trees over Trees

Solving Problems in Subranges • **Problem:** Given n integers  $a_0, a_1, \ldots, a_{n-1}$ , answer q queries of the form

$$\sum_{i=1}^{r-1} a_i$$

for given pairs I, r.

- $n, q \le 100,000$
- Attempt 1 Store the  $a_i$  in an array and answer queries naïvely.
- Complexity Each query could take O(n), so the complexity is O(nq), which is too slow.
- Instead, we need to do some kind of precomputation.

Vectors

Queues

Sets and Map

Heaps

Basic Example

Problems

-----

Range Queries and Updates

Range Trees

Solving Problems in Subranges

- **Algorithm** Construct an array of prefix sums, using (rudimentary) dynamic programming.
- Base case:  $b_0 = 0$ .
- Recurrence:  $b_i = b_{i-1} + a_{i-1}$ .
- This takes O(n) time.
- Now, we can answer every query in O(1) time, so the total complexity is O(n+q).

Range Queries and Updates

Range Trees over Trees

Solving Problems in Subranges • **Problem** Given n integers  $a_0, a_1, \ldots, a_{n-1}$ , answer q queries of the form  $\max a[l, r)$ 

for given pairs I, r.

- $n, q \le 100,000$ .
- Again, the naïve approach answers each query in O(n), so we need to do some kind of precomputation instead.
- Prefix max is unhelpful: knowing max a[0, I) and max a[0, r) says almost nothing about max a[I, r).

Vector

Stacks an Queues

Sets and Map

Heap

Basic Examples

Problems

Union-Find

Range Queries and Updates

Range Trees over Trees

Solving Problems in Subranges

- Max is not "reversible" but it does have a different property: idempotence. This just means max(x, x) = x, i.e: I can apply max as many times as I want to the same element, it does not do anything.
- It's therefore sufficient to cover a range [l, r) with two intervals [l, t) and [s, r) that may overlap.
- If  $l \le t \le s \le r$  then

$$\max a[l,r) = \max(\max a[l,t), \max a[s,r))$$

• So we want to precompute the max of a bunch of intervals, such that any subarray a[l, r) can be written as the union of two of these intervals.

Range Queries and Updates

• **Key Idea:** Precompute the max of all intervals whose lengths are powers of 2.

• This can be done quickly since an interval of length  $2^k$  is the union of two intervals of length  $2^{k-1}$ .

Range Queries and Updates

```
const int N = 100000;
const int LOGN = 18:
int a[N]:
// sparseTable[l][i] = max a[i..i+2^l)
int sparseTable[LOGN][N]:
void precomp(int n) {
   // level 0 is the array itself
   for (int i = 0: i < n: i++)
        sparseTable[0][i] = a[i];
   for (int 1 = 1: 1 < LOGN: 1++) { // inner loop does nothing if 2^l > n
        int w = 1 \iff (1-1); // 2^{(l-1)}
        // a[i,i+2w) is made up of a[i,i+w) and a[i+w,i+2w)
        for (int i = 0; i + 2*w \le n; i++)
            sparseTable[l][i] = max(sparseTable[l-1][i], sparseTable[l-1][i+w]);
```

- Stacks an
- Sets and Map
- Heaps
- Basic
- Example
- Jnion-Fin

# Range Queries and Updates

Range Trees

Solving Problems ir Subranges

- Suppose we now want  $\max a[l, r)$ .
- Let  $p = 2^k$  be the largest power of 2 that is  $\leq r l$ .
- **Key Observation:** since  $p \le r l < 2p$ , we have

$$1 \le r - p < 1 + p \le r,$$

i.e. [l, l+p) and [r-p, r) cover [l, r) (with overlap).

• Hence:

$$\max a[l,r) = \max(\max a[l,l+p),\max a[r-p,r))$$

 But both intervals on the RHS have length a power of 2, so we have precomputed them!

Jnion-Find

Range Queries and Updates

Range Trees over Trees

- For ease of understanding, the illustrations used a full binary tree, which always has a number of nodes one less than a power-of-two.
- This data structure works fine as a complete binary tree as well (all layers except the last are filled).
  - This case is harder to imagine conceptually but the implementation works fine.
  - For each internal node just split the range of responsibility at its midpoint.
- All this means is that padding out the data to the nearest power of two is not necessary.

vectors

Sets and Man

octo una map

неаря

Examples

Problems

-----

Range Queries and Updates

Range Trees

- Since these binary trees are complete, they can be implemented using the same array-based tree representation as with an array heap
  - Place the root at index 0. Then for each node i, its children (if they exist) are 2i + 1 and 2i + 2.
  - Alternatively, place the root at index 1, then for each node i the children are 2i and 2i + 1.
- This works with any binary associative operator, e.g.
  - sum
  - min or max
  - gcd or lcm
  - merge (from merge sort)
    - For a non-constant-time operation like this one, multiply the complexity of all range tree operations by the complexity of the merging operation.

Sets and Ma

Heap

Basic Example

Problems

Official III

Range Queries and Updates

Range Tree over Trees

- We can extend range trees to allow range updates in O(log n) using lazy propagation
- The basic idea is similar to range queries: push the update down recursively into the nodes whose range of responsibility intersects the update range.
- However, to keep our  $O(\log n)$  time complexity, we can't actually update every value in the range.
- Just like we returned early from queries when the query range matched a node's entire range, we cache the update at that node and return without actually applying it.
- When a query or a subsequent update is performed which visits this node you might need to push the cached update one level further down.
- This is not covered in this course.

Heap

Basic Example

Example

Union-Fine

Range Queries and Updates

Range Trees

- We will compute this iteratively using dynamic programming.
- For each index, let best[i] be the length of the longest increasing subsequence ending at index i.
- How do we compute best[i]? Either it's 1 or it extends an
  existing subsequence; in particular, the longest
  subsequence ending at some earlier index j containing a
  smaller array entry.
- Recurrence:

$$best[i] = 1 + max{best[j] | j < i, a[j] < a[i]}.$$

# Example problem: LIS

#### Data Structures

Vectors

Sets and Mar

.

Basic

Example

Union-Fin

Range Queries and Updates

Range Tree over Trees

Solving Problems in Subranges

## Recurrence:

$$best[i] = 1 + max{best[j] | j < i, a[j] < a[i]}.$$

- Direct implementation runs in O(n) per index, i.e.  $O(n^2)$  total; too slow.
- The restriction j < i is handled by the sweep order; only consider best[j] values seen so far.
- But we can't just keep the largest of the best[j] values seen so far, because we have to filter only those where a[j] < a[i].

Range Queries and Updates

• So we want to query, over all j where a[j] < a[i], what is the **max** value of best[*i*].

• This looks like a range query. But over a range of what?

• **Solution:** Range tree indexed by the values a[j]!

# Example problem: LIS

#### Data Structures

Basic Examples

. Example

Jnion-Fin

Range Queries and Updates

Range Trees over Trees

- Let bestWithEnd[h] be the length of the longest subsequence ending at *value h*.
  - Define bestWithEnd[0] = 0 to avoid special cases.
- As we sweep, we maintain a range tree over this array.
   When we get to a new index i,
  - we record that the longest subsequence ending at index i
    has length

$$\mathsf{best}[\mathit{i}] = 1 + \mathsf{max}\,\mathsf{bestWithEnd}[0,\mathit{a}[\mathit{i}]),$$

- and we update bestWithEnd[a[i]] with this best[i] value.
- The final answer is the length of the longest subsequence to finish at any index, or equivalently at any value, so it too can be found by a range query.

Range Queries and Updates

Range Tree over Trees

- Complexity? O(n) range tree queries and updates, each  $O(\log n)$ . Total:  $O(n \log n) \approx 100,000 \cdot 17$ .
- Moral: When trying to solve a problem, be on the lookout for suboperations that might be sped up by data structures. Often take the form of needing to support simple queries.
- Also it is useful to consider range trees over values, not just indices.
- The bound  $h_i \le 100,000$  was not necessary; only the relative order of the  $h_i$  values mattered. So we could have sorted them and replaced each with its rank in the resulting array "coordinate compression".

vectors

Queues

Sets and Map

Heaps

Basic Example

Example

Union-Fine

Range Queries and Updates

Range Tree over Trees

- Alternatively, instead of doing it from left to right, one can solve it in increasing order of values in the array. Then your range tree is over indices not values, and your queries become "what is the largest value in best[0, i)".
- There is also a really elegant solution with a left to right sweep and a sorted stack. Let minEnd[i] store the minimum end value for a subsequence of length i. This is a sorted array (prove it) and we can update it in O(log n) time with binary search.

Range Queries and Updates

Range Trees over Trees

- To support general subtree queries, we will extend our range trees to work on trees.
- The key here is to find an ordering of the vertices such that every subtree corresponds to a range of indices.
- Actually, any sensible DFS ordering already does this.
- DFS processes all nodes in a subtree before returning from the subtree. So as long as we're assigning ids consecutively, a whole subtree should get consecutive indices.

vectors

Sets and Ivial

Пеар

Basic Example

Problems

D 0

and Updates

Range Trees over Trees

- Implementation: In your DFS that creates a representation of the tree, also either preorder or postorder the vertices. Each node should store the range of indices that exists in its subtree.
  - Now build your range tree over these indices. Past this point, you can forget about your tree and just work on your array of indices.
  - To update node u, look up what its index is. Then just update your range tree at indexInRangeTree[u].
  - To query a subtree rooted at v, look up the range of indices in its subtree. Then just query your range tree for the range [startRange[v], endRange[v]).
  - **Moral:** Queries on subtrees are essentially the same as just normal range queries.

Heaps

Basic Examples

Example

Union-Find

Range Queries and Updates

Range Trees over Trees

- For this, we will probably need to store additional metadata.
- Comes down to thinking about what a best solution crossing *m* must look like.
- A subarray crossing the midpoint will be composed of:
  - a suffix of the left half, and
  - a prefix of the right half.
- But remember, any metadata we add must itself be updated in our range tree.
  - Generally this is easier because the metadata is more specific.
  - May need to keep adding more metadata until this stabilises.

Range Tree over Trees

- So for each node we should store the maximum possible sum of a subarray of the form [I, x) and of the form [x, r).
- Call this bestStart[i] and bestEnd[i].
- But now we have the same problem. How do we update bestStart[i] and bestEnd[i] from the 2 children of ??
- Again, we follow the same approach.
- If bestStart[i] is from a subarray contained entirely in the left child then we are done.
- Otherwise, what can it look like?
- **Observation:** It is of the form  $[l, m) \cup [m, x)$  where x corresponds to bestStart[rightChild].

Range Tree over Trees

Solving Problems in Subranges So

- So we now need to maintain sum[i].
- But this is easy, you've seen this many times.
- Phew! We're done now. Only needed to go 3 levels deep!

Range Trees over Trees

```
using namespace std:
const int MAXN = 100100;
struct state {
  long long bestStart, bestEnd, sum, bestSubarray;
// Default value of state is all 0. This is correct for us.
state rt[1<<18]:
state mergeStates(const state& left, const state& right) {
  state ret;
  ret.bestStart = max(left.bestStart, left.sum + right.bestStart):
  ret.bestEnd = max(right.bestEnd, left.bestEnd + right.sum);
  ret.sum = left.sum + right.sum;
  ret.bestSubarray = max(max(left.bestSubarray, right.bestSubarray),
      left.bestEnd + right.bestStart);
  /* in C++11, can instead do ret.bestSubarray = max({left.bestSubarray,
      right.bestSubarray. left.bestEnd + right.bestStartl) */
  return ret:
```

Solving Problems in Subranges • Complexity? Still  $O(\log n)$  for everything, mergeStates is an O(1) operation.

 Moral: While the solution seems involved, the general strategy is very simple. Repeatedly consider what is needed to merge 2 different states and see what additional metadata is necessary. Then hope this stabilizes.

Solving Problems in Subranges • We can apply this technique for many simple problems on a line.

 We can also apply this to some DP problems that have small state space at any point.

 For these, your nodes store matrices detailing how to transition between states.
